# Solving boundary value problems numerically using steepest descent in Sobolev spaces 

W. T. Mahavier

March 15, 2011

#### Abstract

Elementary boundary value problems are used as a vehicle to introduce upper level undergraduate students or first year graduate students to descent algorithms. The paper is expository in nature and includes references for Euclidean and Sobolev steepest descent while serving as an introduction to optimization techniques such as variable metric and conjugate gradient methods. Numerical algorithms for solving boundary value problems with both Euclidean and Sobolev descent are developed. Results for constrained, unconstrained, and singular problems are displayed and properties of descent algorithms are outlined.

## 1 Introduction

Let $k_{1}, k_{2}, k_{3}, a, b \in \mathbf{R}$ with $a<b$. Let $f:[a, b] \times \mathbf{R} \rightarrow \mathbf{R}$ be differentiable with respect to the second variable. This paper illustrates a numerical method for solving the class of first order, boundary value problems with linear inhomogeneous boundary conditions,

$$
\begin{gather*}
y^{\prime}(t)=f(t, y(t))  \tag{1}\\
k_{1} * y(a)+k_{2} * y(b)=k_{3} .
\end{gather*}
$$

The paper illustrates a simple application of a universal procedure. Written while the author was a graduate student, it is accessible to upper-level undergraduate and first year graduate students and was used by the author to supplement traditional topics in a two semester first year graduate numerical methods course. By incorporating the material of this paper, students were introduced to finite dimensional vector space theory in such a way that the concepts generalized to infinite dimensional settings [M3]. Because the paper rests heavily on results from linear algebra and advanced calculus, we use bullets to highlight these results as they are used.

Steepest descent is a highly versatile technique. It is used for finding a relative minimum (or maximum) of a function and is often used to find a starting point for Newton's method [B]. Traditional texts on differential equations and numerical methods consider Euler, Taylor, and Runga-Kutta
methods for initial value problems, final value problems, and two point boundary value problems. To demonstrate the versatility of descent methods, we first consider the class of problems, Equation 1, which incorporates not only initial and final value problems but also problems with mixed boundary conditions that previously mentioned methods are not able to handle. Section 4 includes examples of unconstrained, constrained, non-linear, and singular problems all of which utilize the same algorithm.

Given a function, $f$, and a point in the domain of the function, $x_{0}$, the process is to generate a sequence of points in the domain of the function which converge to a point at which $f$ attains a relative minimum. The sequence is generated by setting $x_{k+1}=x_{k}-\delta_{k} \nabla f\left(x_{k}\right)$ for $k=0,1,2, \ldots$ where $\delta_{k}$ is some small (perhaps optimally chosen) positive number. More thorough introductory information on steepest descent may be found in $[\mathrm{L}]$, $[\mathrm{O}]$, or $[\mathrm{R}]$. Using steepest descent to solve differential equations requires that we determine a function whose minima represent solutions to the differential equation. Such methods were first introduced by Cauchy in [C], however, with the advent of computers it was discovered that such methods were numerically inefficient. Modifications such as conjugate gradient and variable metric methods were introduced to speed up the convergence. In the introduction to Hestenes' book, [HM], he states, "Variable metric methods are considered by many to be the most effective technique for optimizing a nonquadratic function." Sobolev steepest descent is an example of this technique where gradients are based not on Euclidean space but on Sobolev spaces which will be defined in this paper. In Section 4 we will see that the choice of the gradient has considerable impact on the speed of convergence of the algorithm.

Sobolev steepest descent originates with J. W. Neuberger and this paper rests firmly on his work. In [JWN1] sufficient conditions are given for the convergence of constrained steepest descent utilizing the Sobolev gradients in continuous spaces. In [M2] a convergence poof is given for discrete spaces such as those in this paper and in [M3] results for first and second order boundary value problems with linear singularities are considered. Additional theory on Sobolev steepest descent for systems of ordinary differential equations may be found in [JWN2] and references for the application of the method to partial differential equations include [JWN3], [JMN], and [M4]. Pressing applied problems have been addressed using these methods in [D], [K], and [G]. A general reference for Sobolev spaces is [A].

The body of the paper falls into three sections. Section 2 illustrates Euclidean steepest descent for the class of problems above. Section 3.1 and 3.2 outline Sobolev descent with and without boundary conditions, respectively. Section 4 illustrates the technique with several examples.

## 2 Euclidean Descent

Let $\|\cdot\|$ denote the Euclidean norm and denote $x \in \mathbf{R}^{m}$ by $x=\left(x_{1}, \ldots, x_{m}\right)$. Let $k_{1}, k_{2}, k_{3}, a, b \in \mathbf{R}$ with $a<b$. Let $f:[a, b] \times \mathbf{R} \rightarrow \mathbf{R}$ be differentiable with respect to the second variable. Suppose $n$ is the number of divisions we wish to partition the interval $[a, b]$ into and $\delta=(b-a) / n$.

- If $U$ and $V$ are finite dimensional vector spaces and $L(U, V)$ denotes the set of all linear operators from $U$ to $V$ then every $M \in L(U, V)$ has a matrix representation.

To simplify our notation, we define discretized versions of the identity and derivative operators. It will be simplest to think of $D_{0}$ and $D_{1}$ as their matrix representations. Let $D_{0}$ and $D_{1} \in$ $L\left(\mathbf{R}^{n+1}, \mathbf{R}^{n}\right)$ be defined by

$$
D_{0}(x)=\left(\begin{array}{c}
\frac{x_{1}+x_{2}}{2} \\
\vdots \\
\frac{x_{n}+x_{n+1}}{2}
\end{array}\right) \quad \text { and } \quad D_{1}(x)=\left(\begin{array}{c}
\frac{x_{2}-x_{1}}{\delta} \\
\vdots \\
\frac{x_{n+1}-x_{n}}{\delta}
\end{array}\right) .
$$

In order to solve the differential equation $y^{\prime}(t)=f(t, y(t))$ we construct a function whose minimum is a solution to the equation. Let $y \in \mathbf{R}^{n+1}$ and for all $k=1,2, \ldots, n+1$, let $t_{k}=a+(k-1) * \delta$ and $f_{k}=f\left(t_{k}, y_{k}\right)$. Define $\phi:\left(\mathbf{R}^{n+1},\|\cdot\|\right) \rightarrow \mathbf{R}$ by

$$
\phi(y)=\left\|D_{1} y-D_{0} f\right\|^{2} / 2=1 / 2 \sum_{k=1}^{n}\left(\frac{y_{k+1}-y_{k}}{\delta}-\frac{f_{k}+f_{k+1}}{2}\right)^{2}
$$

If we are able to determine a point, $y$, in the domain of $\phi$ that satisfies $\phi(y)=0$ then we have $D_{1} y=D_{0} f$. This equation is the discrete version of the differential equation, $y^{\prime}(t)=f(t, y(t))$, that we desired to solve. As we outlined in the introduction, we will minimize $\phi$ via successive approximations. The function $\phi$ will remain the same for both the Euclidean and Sobolev descent.

Algorithm 1:

1. Choose $y \in \mathbf{R}^{n+1}$.
2. Compute $\nabla \phi(y)=\left(\frac{\partial \phi}{\partial y_{1}}, \frac{\partial \phi}{\partial y_{2}}, \ldots \frac{\partial \phi}{\partial y_{n+1}}\right)$
3. Determine $h$ which minimizes $\phi(y-h \nabla \phi(y))$ (or try $\mathrm{h}=.01$ ).
4. Let $y^{\text {new }}=y-h \nabla \phi(y)$.
5. If $\left\|y^{\text {new }}-y\right\|<\epsilon$, we have a solution; else, put $y=y^{\text {new }}$ and repeat steps 3 through 5 .

## 3 Sobolev Descent

The heart of the paper is that $\mathbf{R}^{n+1}$ may be considered as two distinct spaces if we place two different norms on $\mathbf{R}^{n+1}$. Thus you should think of the difference between this section and the last one as follows. In the previous section we introduced a pair which were intimately related: The space, $\left(\mathbf{R}^{n+1},\|\cdot\|\right)$, and the gradient of $J$ based on the space, $\nabla J$. In this section we introduce a second intimately related pair: The space, $\left(\mathbf{R}^{n+1},\|\cdot\|_{H}\right)$, and the gradient of $J$ based on this space, $\nabla_{s} \phi J$. In Section 4 you will see that descent based on these two different spaces yields quite different results in terms of the necessary number of iterations and the amount of time required to solve a problem.

### 3.1 Solving $y^{\prime}(t)=f(t, y(t))$

In this section we introduce the notation and theory needed to perform descent in the simplest case; the case where we have no boundary conditions. Introducing the material in this way lays the foundation which for the transition to the case with boundary conditions.

Our space is $\left(\mathbf{R}^{n+1},\langle\cdot, \cdot\rangle_{s}\right)$ where $\langle\cdot, \cdot\rangle_{s}$ denotes the discretized Sobolev inner product defined by

$$
\begin{aligned}
&\langle u, v\rangle_{s}=\left\langle D_{0}(u), D_{0}(v)\right\rangle+\left\langle D_{1}(u), D_{1}(v)\right\rangle= \\
& \sum_{k=1}^{n}\left(\frac{u_{k+1}+u_{k}}{2}\right)\left(\frac{v_{k+1}+v_{k}}{2}\right)+\left(\frac{u_{k+1}-u_{k}}{\delta}\right)\left(\frac{v_{k+1}-v_{k}}{\delta}\right)
\end{aligned}
$$

for all $u, v \in \mathbf{R}^{n+1}$. Define $D \in L\left(\mathbf{R}^{n+1}, \mathbf{R}^{2 n}\right)$ by $D(x)=\binom{D_{0}(x)}{D_{1}(x)}$ and $\|\cdot\|_{s}=\sqrt{\langle\cdot, \cdot\rangle_{s}}$. Observe that $D$ relates the Euclidean and Sobolev norms by $\|\cdot\|_{s}=\|D(\cdot)\|$.

- (Halmos, $[\mathrm{HP}])$ If $F$ is a linear functional on the finite dinensional inner product space, $(V,\langle\cdot, \cdot\rangle)$ then there exists a unique element $z \in V$ which satisfies, $F(x)=\langle z, x\rangle$ for all $x \in V$.
- If $F$ is a differentiable function on $\mathbf{R}^{n}$ and $x \in \mathbf{R}^{n}$ then $F^{\prime}(x)$ is a linear functional.

We use these two facts to construct our gradient based on the new inner product space, $\left(\mathbf{R}^{n+1},\langle\cdot, \cdot \cdot\rangle_{s}\right)$ Since $\left(\mathbf{R}^{n+1},\langle\cdot, \cdot\rangle_{s}\right)$ is a complete inner product space and $\phi^{\prime}(u)$ is a linear functional, by ??, for every $u \ni \mathbf{R}^{n+1}$ there exists a unique element, $z$, depending on $\phi$ and $u$ which satisfies $\phi^{\prime}(u)(h)=\langle z, h\rangle_{s}$ for all $h \ni \mathbf{R}^{n+1}$. We define $\nabla_{s} \phi(u)$ to be this element. In order to compute this new gradient, we prove a threorm which relates the Sobolev gradient to the Euclidean gradient.

Theorem 1 If $\langle\cdot, \cdot\rangle_{s}$ denotes the discretized Sobolev inner product on $\mathbf{R}^{n+1}$ and $\langle\cdot, \cdot\rangle$ represents the standard inner product on $\mathbf{R}^{n+1}$ then $\exists A \in L\left(\mathbf{R}^{n+1}, \mathbf{R}^{n+1}\right) \ni\langle x, y\rangle_{s}=\langle A x, y\rangle=\langle x, A y\rangle \forall x, y \in$ $\mathbf{R}^{n+1}$. Moreover, $A=D^{t} D$ and $A \nabla_{s} \phi(x)=\nabla \phi(x) \quad \forall x \in \mathbf{R}^{n+1}$.

Proof.

- If $(V,\langle\cdot, \cdot\rangle)$, is a finite dimensional vector space, then $\left.\langle M x, y\rangle=<x, M^{t} y\right\rangle$ for every linear operator, $M$ on $V$.

Using this fact and the linearity of the inner product,

$$
\begin{aligned}
\langle x, y\rangle_{s} & =\left\langle D_{0} x, D_{0} y\right\rangle+\left\langle D_{1} x, D_{1} y\right\rangle \\
& =\left\langle D_{0}{ }^{t} D_{0} x, y\right\rangle+\left\langle D_{1}{ }^{t} D_{1} x, y\right\rangle \\
& =\left\langle\left(D_{0}{ }^{t} D_{0}+D_{1}{ }^{t} D_{1}\right) x, y\right\rangle
\end{aligned}
$$

$\forall x, y \in \mathbf{R}^{n+1}$. Therefore, $A=D^{t} D$. Given $u \in \mathbf{R}^{n+1}$ we have

$$
\begin{aligned}
\langle\nabla \phi(u), h\rangle & =\phi^{\prime}(u)(h) \\
& =\left\langle\nabla_{s} \phi(u), h\right\rangle_{s} \\
& =\left\langle A \nabla_{s} \phi(u), h\right\rangle
\end{aligned}
$$

$\forall h \in \mathbf{R}^{n+1}$. Consequently, $A \nabla_{s} \phi(x)=\nabla \phi(x) \forall x \in \mathbf{R}^{n+1}$ and the theorem is proved.

We now outline the method. Compute the matrix, $A$, which is diagonally dominant and tridiagonal. Choose an initial guess, $y$. Compute the standard gradient, $\nabla \phi(y)$, and solve the linear system from Theorem 1, $A \nabla_{s} \phi(y)=\nabla \phi(y)$, for the Sobolev gradient, $\nabla_{s} \phi(y)$. Follow the negative of this direction an 'optimal' distance, $h$. Since we seek a zero of $\phi$, 'optimal' implies that $\phi\left(y-h \nabla_{s} \phi(y)\right)$ is minimized. Consider the distance between the new point, $y^{\text {new }}$, and $y$. If this distance is less than $\epsilon$, consider $y^{\text {new }}$ a solution, else repeat the process with $y^{\text {new }}$ as an initial guess.

Algorithm 2:

1. Compute the matrix, A.
2. Choose $y \in \mathbf{R}^{n+1}$.
3. Compute the gradient of $\phi$ at $y, \nabla \phi(y)$.
4. Solve $A \nabla_{s} \phi(y)=\nabla \phi(y)$ for $\nabla_{s} \phi(y)$.
5. Determine $h$ which minimizes $\phi\left(y-h \nabla_{s} \phi(y)\right)$.
6. Let $y^{\text {new }}=y-h \nabla_{s} \phi(y)$.
7. If $\left\|y^{\text {new }}-y\right\|<\epsilon$, we have a solution; else, put $y=y^{\text {new }}$ and repeat steps 3 through 7 .

We have now outlined both Euclidean and Sobolev descent for Equation 1 in the simplest case; the case with no boundary conditions. At this point the reader should be able to write a short code which verifies the results for Sobolev descent in Table 1 of Section 4.1.
3.2 Solving $y^{\prime}(t)=f(t, y(t))$ with the Boundary Conditions $k_{1} * y(a)+k_{2} *$ $y(b)=k_{3}$.

Let $\mathbf{R}_{0}^{n+1}=\left\{x \in \mathbf{R}^{n+1}: k_{1} * x_{1}+k_{2} * x_{n+1}=0\right\}$ and let $\pi_{s}$ denote the orthogonal projection of $\mathbf{R}^{n+1}$ onto $\mathbf{R}_{0}^{n+1}$ under the Sobolev inner product.

A naive generalization of the case without boundary conditions follows. Start with an initial guess, $y$. Compute the Sobolev gradient, $\nabla_{s} \phi(y)$, and the projection, $\pi_{s}$. Project $\nabla_{s} \phi(y)$ onto $\mathbf{R}_{0}^{n+1}$ under $\pi_{s}$ and follow the negative of this direction an optimal distance, $h$. Consider the distance between the new point, $y^{\text {new }}$, and $y$. If this distance is less than $\epsilon$, consider $y^{\text {new }}$ a solution, else repeat the process with $y^{\text {new }}$ as our initial guess.

Algorithm 3:

1. Compute the matrix, A
2. Choose $y \in \mathbf{R}^{n+1}$ such that $y$ satisfies the boundary conditions.
3. Compute the gradient of $\phi$ at $y, \nabla \phi(y)$.
4. Solve $A \nabla_{s} \phi(y)=\nabla \phi(y)$ for $\nabla_{s} \phi(y)$.
5. Compute the Sobolev projection, $\pi_{s}$, and project $\nabla_{s} \phi(y)$ onto $\mathbf{R}_{0}^{n+1}$.
6. Determine $h$ which minimizes $\phi\left(y-h \pi_{s} \nabla_{s} \phi(y)\right)$.
7. Let $y^{\text {new }}=y-h \pi_{s} \nabla_{s} \phi(y)$.
8. If $\left\|y^{\text {new }}-y\right\|<\epsilon$ we have a solution; else, put $y=y^{\text {new }}$ and repeat steps 3 through 8 .

Since $\pi \nabla_{s} \phi(y)$ is in the linear subspace, $\mathbf{R}_{0}^{n+1}, y^{n e w}$ will also be in $\mathbf{R}_{0}^{n+1}$, thus guaranteeing that boundary conditions are exactly maintained at each iteration. To implement this algorithm we would need an explicit definition for the projection $\pi_{s}$. To avoid this computation, we combine steps 4 and 5 in order to compute the quantity $\pi_{s} \nabla_{s} \phi(y)$ by solving one system of $n+1$ equations. This allows us to avoid computing the projection $\pi_{s}$ directly. We now exhibit the method used to compute $\pi_{s} \nabla_{s} \phi(y)$. First, recall two facts from linear algebra:

- If $\pi$ is a projection and $\langle\cdot, \cdot\rangle$ is an inner product then $\langle\pi x, y\rangle=\langle x, \pi y\rangle$.
- If $S$ is a subspace of the inner product space $(V,\langle\cdot, \cdot\rangle)$ and $v \in V$ then the orthogonal projection of $v$ onto $S$ is the element $s \in S$ which minimizes, $\{\|v-s\|: s \in S\}$.

Let $g=\nabla_{s} \phi(y)$ and define $\gamma: \mathbf{R}_{0}^{n+1} \rightarrow \mathbf{R}$ by $\gamma(x)=\|x-g\|_{s}^{2} / 2$. Minimizing $\gamma$ over $\mathbf{R}_{0}^{n+1}$ corresponds to determining $x \in \mathbf{R}_{0}^{n+1}$ such that $x=\pi_{s} \nabla_{s} \phi(y)$. Let $\pi_{e}$ denote the orthogonal Euclidean projection onto $\mathbf{R}_{0}^{n+1}$.

$$
\begin{aligned}
\gamma(x) & =\|x-g\|_{s}^{2} / 2 \\
& =\|D(x-g)\|^{2} / 2
\end{aligned}
$$

and

$$
\begin{aligned}
\gamma^{\prime}(x)(z) & =\langle D(x-u), D(z)\rangle \\
& =\left\langle D^{t} D(x-u), z\right\rangle \\
& =\left\langle D^{t} D(x-u), \pi_{e}(z)\right\rangle \\
& =\left\langle\pi_{e} D^{t} D(x-u), z\right\rangle .
\end{aligned}
$$

Therefore $\gamma^{\prime}(x)(z)=0 \quad \forall z \in \mathbf{R}_{0}^{n+1}$ if and only if $\pi_{e} D^{t} D(g)=\pi_{e} D^{t} D(x)$. Substituting $A=D^{t} D$, $g=\nabla_{s} \phi(y)$, and $A \nabla_{s} \phi(y)=\nabla \phi(y)$ into this equation yields $\pi_{e} A x=\pi_{e} \nabla \phi(y)$. The solution to this equation is the desired quantity, $x=\pi_{s} \nabla_{s} \phi(y)$.

Having avoided the direct computation of the projection, $\pi_{s}$, we must still determine the projection, $\pi_{e}$. Yet, we may compute $\pi_{e}$ by defining $\psi(x)=\|x-u\|^{2} / 2$ and minimizing $\psi$ over $\mathbf{R}_{0}^{n+1}$ to obtain

$$
\pi_{e}(x)=\left(\frac{k_{2}\left(k_{2} x_{1}-k_{1} x_{n+1}\right)}{k_{1}^{2}+k_{2}^{2}}, x_{2}, x_{3}, \ldots, x_{n}, \frac{-k_{1}\left(k_{2} x_{1}-k_{1} x_{n+1}\right)}{k_{1}^{2}+k_{2}^{2}}\right) .
$$

Certain values of $k_{1}$ and $k_{2}$ cause numerical difficulties. For example, $\pi_{e}$ is not defined if $k_{1}=k_{2}=0$. If $k_{1}$ and $k_{2}$ are not both zero, $\pi_{e}$ is well defined, yet when we apply the projection to the matrix, $A$, the first and last rows of the projected matrix are linearly dependent. Let us look at each of four possible cases. If $k_{1}=k_{2}=0$, we do not wish to use the projection as we have no boundary conditions; we are actually solving the problem outlined in Section 3.1 where $\pi_{e}$ was neither defined nor needed. If $k_{1}=0$ and $k_{2} \neq 0$ we are considering the final value problem, $y(b)=k_{3} / k_{2}$. Here, $\pi_{e}$ zeroes out the last row of the matrix $A$. Therefore we replace this row by the data, $\left(0, \ldots, 0, k_{2}\right)$, and zero out the final entry of the gradient vector, $\nabla \phi(y)$, before solving the system. If $k_{1} \neq 0$ and $k_{2}=0$, we are considering the initial value problem, $y(a)=k_{3} / k_{1}$. In this case $\pi_{e}$ zeroes out the first row of the matrix $A$ and we replace this row by the data, $\left(k_{1}, 0, \ldots, 0\right)$ and zero out the first entry of the gradient vector, $\nabla \phi(y)$, before solving the system. Finally if both $k_{1}$ and $k_{2}$ are non-zero then we replace the last row by the boundary data, $\left(k_{1}, 0, \ldots, 0, k_{2}\right)$ and zero out the last entry of the gradient vector, $\nabla \phi(y)$, before solving the system.

A revised algorithm follows.

1. Compute the matrix, $A$, and the projection, $\pi_{e}$.
2. Choose $y \in \mathbf{R}^{n+1}$ such that $y$ satisfies the boundary conditions.
3. Compute the gradient of $\phi$ at $y, \nabla \phi(y)$.
4. Apply $\pi_{e}$ to the matrix, $A$, and the gradient, $\nabla \phi(y)$.
5. Make $\pi_{e} A$ nonsingular by replacing the necessary rows.
6. Solve $\pi_{e} A\left(\pi_{s} \nabla_{s} \phi(y)\right)=\pi_{e} \nabla \phi(y)$ for $\pi_{s} \nabla_{s} \phi(y)$.
7. Determine $h$ which minimizes $\phi\left(y-h \pi_{s} \nabla_{s} \phi(y)\right)$.
8. Let $y^{\text {new }}=y-h \pi_{s} \nabla_{s} \phi(y)$.
9. If $\left\|y^{\text {new }}-y\right\|<\epsilon$, we have a solution; else, put $y=y^{\text {new }}$ and repeat steps 3 through 9 .

## 4 Examples

In this section we consider three problems. The first illustrates the algorithm on the differential equation $y^{\prime}=y$. We consider the unconstrained problem (no boundary conditions), an initial value problem, a final value problem, and a mixed boundary value problem. In the second section we consider a nonlinear equation with various boundary conditions. Because the first two examples are simple differential equations which (with the exception of the mixed boundary conditions) could easily be solved by methods traditionally taught in differential equations or numerical methods courses, in the last section, we address Legendre's equation which is singular at $x=1$.

Table 1: The simplest differential equation

| $\mathbf{y}^{\prime}=\mathbf{y}$ |  |  |  | $\mathbf{N}=\mathbf{1 0}^{-\mathbf{2}}$ |
| :---: | :---: | :---: | :---: | :---: |
| Gradient | Iterations | Seconds | Average Absolute Error | Maximum Absolute Error |
| $E$ | 1845 | 3 | $5.9 \times 10^{-1}$ | $9.2 \times 10^{-1}$ |
| $S$ | 4 | 1 | $5.6 \times 10^{-4}$ | $7.5 \times 10^{-4}$ |

| $\mathbf{y}^{\prime}=\mathbf{y}$ |  |  | $\epsilon=\mathbf{1 0}^{-\mathbf{4}}$ | $\mathbf{N}=\mathbf{1}, \mathbf{0 0 0}$ |
| :---: | :---: | :---: | :---: | :---: |
| Gradient | Iterations | Seconds | Average Absolute Error | Maximum Absolute Error |
| $E$ | 14,777 | 27 | $6.6 \times 10^{-3}$ | $9.2 \times 10^{-3}$ |
| $S$ | 6 | 1 | $8.7 \times 10^{-6}$ | $1.0 \times 10^{-5}$ |

| $\mathbf{y}^{\prime}=\mathbf{y}$ |  |  | $\epsilon=\mathbf{1 0}^{-\mathbf{6}}$ | $\mathbf{N}=\mathbf{1 0}, \mathbf{0 0 0}$ |
| :---: | :---: | :---: | :---: | :---: |
| Gradient | Iterations | Seconds | Average Absolute Error | Maximum Absolute Error |
| $S$ | 8 | 22 | $1.9 \times 10^{-7}$ | $2.6 \times 10^{-7}$ |

### 4.1 The simplest of examples

All of the results in this section apply to the differential equation, $y^{\prime}=y$ on the interval $[0,1]$. A desired accuracy of $\epsilon$ requires that $\left\|y^{\text {new }}-y\right\|<\epsilon$. Average absolute error is defined by

$$
\text { average absolute error }=\frac{1}{n+1} \sum_{i=1}^{n+1}\left|y_{k}^{\text {true }}-y_{k}^{\text {approx }}\right|
$$

and maximum absolute error is given by

$$
\text { maximum absolute error }=\max \left\{\left|y_{k}^{\text {true }}-y_{k}^{\text {approx }}\right|: k=1,2, \ldots, n+1\right\}
$$

The unconstrained case: This case is included because the results in Table 1 may be obtained without reading beyond Section 3.1 We first consider the problem with no boundary conditions starting with a constant initial function, $y_{0}=3$. Since all solutions are of the form $c * E$ where $E(t)=e^{t}$ on $[0,1]$, we may determine the solution to which each process will converge by minimizing the functions, $\gamma_{E}(c)=\left\|y_{0}-c E\right\|^{2}$ for Euclidean descent and $\gamma_{S}(c)=\left\|y_{0}-c E\right\|_{S}^{2}$ for Sobolev descent. These functions are quadratic in $c$ hence the minimum is easily obtained.

Table 1 indicates the difference between Euclidean (E) and Sobolev (S) descent. Several observations are in order. First, Sobolev descent outperforms Euclidean descent in terms of the time required to solve the problem, the accuracy achieved, and the number of iterations. Second, as we increase the number of divisions from 100 to 1,000 Euclidean descent requires approximately 9 times the number of iterations to converge. On the other hand, even as we increase the number of divisions from 100 to 10,000 , Sobolev descent requires only twice the number of iterations. Third, the order of magnitude of the error in the solution obtained via Sobolev descent is comparable to the desired accuracy while for Euclidean descent the achieved accuracy is consistently lower than the desired accuracy. Finally, for $\mathrm{N}=10,000$ we have omitted Euclidean descent as convergence was not obtained in this case.

For the remainder of the problems in this section we do not include the results for Euclidean descent,
however, results from the previous example are typical for each of the following problems.

The initial value problem: If we consider the problem starting with the constant initial function, $y_{0}=3$ and the desired initial condition, $y(0)=3$, we obtain convergence in 9 iterations. The maximum error for this case is $2.3 E-02$. The same problem with an increased accuracy of .001 converges in 13 iterations with a maximum error of $2.3 E-03$.

The final value problem: If we consider the problem starting with the constant initial function, $y_{0}=3$ and the desired final condition, $y(1)=3$, we obtain convergence in 4 iterations. The maximum error for this case is $4.0 E-04$.

The mixed boundary value problem: Consider the boundary condition, $y(0)+y(1)=e+1$. With an initial guess which is the line between $(0,0)$ and $(1, e+1)$, convergence occurs in 4 iterations. The maximum error for this case is $4.0 E-06$. Similar results are achieved if $y(0)+y(1)=e+1$ is replaced by $.5 y(0)+.5 y(1)=(e+1) / 2$.

### 4.2 A nonlinear mixed boundary value problem

The results in this section apply to the differential equation, $y^{\prime}(t)=(t+y(t))^{2}$ with 100 subdivisions. Observe that $y(t)=\tan (t)-t$ satisfies the differential equation.

The initial value problem: Given the initial function, $y_{0}=0$ on $[0,1]$ and a desired initial condition, $y(0)=0$, we obtain convergence for a desired accuracy of .01 in 17 iterations with a maximum error of $1.6 E-02$, corresponding to less than 3 percent error.

The mixed boundary value problem: For our last example we consider the interval $[-\pi / 4, \pi / 4]$ with the poor initial guess $y_{0}(t)=-t$, and ask for a solution satisfying the mixed boundary conditions, $y(-\pi / 4)+y(\pi / 4)=0$ and an accuracy of .001 . We obtain convergence in 6 iterations with a maximum error of $3.0 E-03$. Percent error is meaningless in this case as the value of the solution is zero at zero; however, the maximum error occurs at zero and the approximated value at zero is less than $3.0 E-07$.

### 4.3 Legendre's equation

As a final example we present results for Legendre's equation which has a singularity at $t=1$. Table 2 includes data for descent based on three distinct gradients. The first two gradients are the Euclidean (E) and Sobolev (S) gradients as introduced in previous sections. The last gradient is based on a weighted Sobolev $\left(S_{w}\right)$ inner product, i.e. a gradient custom built for the singular nature of the problem at hand. Detailed information on the modifications made to the algorithm may be found in [M3]. A general reference on weighted Sobolev spaces is [KA].

The problem is to solve, $\left(\left(1-t^{2}\right) u^{\prime}\right)^{\prime}+2 u=0$ on $I$ with $u(0)=0, u(1)=1$, and $u \in C_{I}^{2}$. General solutions are $u(t)=c_{1} t+\frac{c_{2}}{2} t \ln \left(\frac{1+t}{1-t}\right)$ and only $u(t)=t$ satisfies the boundary conditions.

Table 2: Legendre's Equation

For the second and third tables, we increase both the number of divisions of the interval and decrease the desired accuracy. The second table omits the Euclidean descent results which appeared in the first table as Euclidean descent will not converge for the tighter stopping criteria. Likewise, the third table omits both the Euclidean and Sobolev descent because neither converge for the still tighter stopping criteria.

These tables demonstrate clearly the advantage of applying gradients for a given problem. We see that the weighted Sobolev descent outperforms Sobolev descent which in turn outperforms Euclidean descent in terms of the time and the number of iterations required to achieve a desired accuracy.

## 5 Conclusions

In this section we comment on a few of the nicer properties of descent algorithms that we have observed. Tables 1 and 2 support these observations, but do not represent isolated incidences. The author has applied the method to some 50 or more problems and the following traits appear consistently.

1. For the problems presented weighted Sobolev descent outperforms Sobolev descent which in turn outperforms Euclidean descent.
2. Sobolev descent is not sensitive to the number of divisions of the interval (see Table 1). Given a desired accuracy, the number of iterations required for convergence of Sobolev descent does not increase significantly as the number of divisions is increased. Such properties are particularly significant when considering partial differential equations where the number of grid points is greatly increased and experimental runs may use courser grids.
3. The same statement cannot be made of Euclidean descent.
4. The average absolute error and maximum absolute error for both Sobolev and weighted Sobolev descent are on the order of magnitude of the residual. Restated, if the stopping criteria is $\left\|y^{\text {new }}-y\right\|<\epsilon$ for successive iterations $y$ and $y^{\text {new }}$ then we may expect that upon convergence to a solution, $y^{\text {approx }}$, we have

$$
\frac{1}{n+1} \sum_{i=1}^{n+1}\left|y_{k}^{\text {true }}-y_{k}^{\text {approx }}\right| \cong \epsilon
$$

and

$$
\max \left\{\left|y_{k}^{\text {true }}-y_{k}^{\text {approx }}\right|: k=1,2, \ldots, n+1\right\} \cong \epsilon
$$

5. Exact boundary conditions are maintained at each step of the descent process, guaranteeing exact boundary conditions for the solution. This is a consequence of the algorithm. Because we perturb our solutions by elements which satisfy zero boundary conditions, the initial boundary conditions are never changed.
6. The generalization of the code to handle singular multiple point boundary value problems such as $(t-1 / 4)(t-3 / 4) y^{\prime}=y$ on $[0,1]$ with constraints, $y(1 / 4)=1$, and $y(3 / 4)=2$, requires only a slightly more difficult computation of the projection, $\pi_{e}$.
7. Generalization of the code to partial differential equations is type independent, [JWN4], [M4]. Many numerical methods which solve partial differential equations use theory which applies only to elliptic, parabolic, or hyperbolic equations while many pressing problems address differential equations which of mixed type.
